by E. ERNEst GREEN, F.E.S.,<br>Government Entomologist, Royal Botanic Gardens, Peradeniya, Ceylon.

The following notes are founded upon an interesting series of Coccide collected in June by Prof. A. Zimmermann, of the Botanic Gardens, Buitenzorg. Many of the species (and some of the genera) are new to science; others are representative partly of the Indian and partly of the Australian fana; the remainder are cosmopolitan forms that have followed civilization throughout the world.

Lecanium tenebricophiluas, sp. nov. (fig. 1).
Adult $f$, bright eastaneous to dark brown ; strongly eonvex; irregularly hemispherical, with posterior extremity abmptly depressed (fig. $1 b$ ), the anal seales situate in the centre of this depressed area. Stigmatic clefts moderately deep ; the spiracle impinging on the eleft (fig. 1 c). No stigmatie spines. Limbs small, but

Fig. 1.
fully developed. Antenna with seven or eight joints, the former being probably
the normal number; but there is usually a more or less complete subrlivision of either the terminal or the penultimate joint. Some stont hairs at extremity. Formula very variable, no two examples agreeing ; 2nd usnally longest, sometimes equal to 3rd; 5th and 6 th, or 6 th and 7 th shortest. Legs with a deep eonstriction near the middle of the tarsus, simulating a joint, a somewhat similar false joint being apparent near the base of the tibia. Foot with four digitules; the ungnals spatulate ; the tarsals fine knobbed lairs. Plates of anal operculum (fig. 1 e) with inner edge longest; outcr edge shortest and rounded; base straight, three-quarters the length of inner edge. (My examples are not in sufficiently good preservation to enable me to determine the number of hairs on the anal ring). Anal cleft rather more than one-quarter total length of insect. Margin with very minute ineonspicnous simple hairs at considerable intervals. Derm thiekly set with oval translucent pores, separate from each other by a little more thatn their longest diameter (fig. 1 d ).

Length, 4 to 5 mm . ; breadth, 3 to 4 mm . ; height, averaging 3 mm .
Other stages unknown.
Habitat: Within the tumnels formed in branches of Erythrina lithosperma by some boriug caterpillar or beetle (fig. 1 a).

The Coccids are entirely concealed, attached to the walls of the tumnel, sometimes at a distance of from 6 to 10 inches from the exit. Prof. Zimmermann informs me that they are always attended by ants. (Coll. Zimm., No. 1).

Lecanium (Satssetia) hemispiericum, Targ.
On Coffera arabica (No. 20).
Lecanium (Eutecanium) psimit, Green.
On Jambosa sp. (No. 28).
A formal description of this species appears in Part III, "Coccidce of Ceylon."

Lecanium (Paradecanitm) expansum, Green.
On Zingiberaceons plant (No. 25) and Lepidadenia wightiana (No. 95).

Lecanium expansum, var. metahitede, n. var.
Differs from type in having a beautiful iridescent metallic sheen on dorsum of living insect, disappearing after treatment with potash. Margin closely stippled with dark opaque spots. On Myristica fragrans (No. 38).

Lecanidm expansum, var. Jatinteda, n. var.
Differs from type in having a minute but regular dermal retienlation. On Anomianthus hetcrocarpus (No. (i4).

Lecanium expansum, vat, rotundem, $n$. var.
Smaller than type and circular in outline. Margin stippled as in metallicum. On Rhizophora mucronata (No. 82).

## Lecanium (Saissetia) nigrem, Nietner.

On Hever brasiliensis (No. S0).

## Lecanjum (Eucalymnatus) tessellatum, Sigu.

These specimens agree with Signoret's type in having no median dorsal suture. But the median area is densely chitmous and the division may be merely obscured. On Eriodendron anfractuosum (No. 83).

## Lecanium (Saissetia) olee, Berin.

On Erythrina lithosperma (No. 99).
Pulvinaria maxima, sp. nov. (fig. 2).
Dried examples pale fulvons, probably greenish in life. Orisae profuse, white, flattish ; sometimes extending to a length of 20 mm .

Adult $\&$ irregularly oval; margins malulating; broadest across posterior half. Margin with a close fringe of stont spines (fig. $2 a$ ), whieh, in all my examples, are irregularly trmeate, as if broken,

Fig. 2.
exeept at the stigmatie clefts, where they are longer and sharply pointed. Limbs well developed. Antenna (fig. $2 b$ ) eight jointed, 3 rd longest, 7 th and 8 th shortest.

Tarsus scareely half length of tibia. Plates of anal opereulnm rather marrow and acuminate; base and outer eflge approximately equal ; outer angle obtuse. Anal ring with six stout hairs. Derm elosely set with large conspicnous oval or subcircular translucent cells. Length, 6 to 9 mm ; breadth, t to 5.75 mm .

Irabitat: On stems of Erythrina lithosperma (No. 2.2).
This inseet is the eriant of its kinc, but is closely approached by P. mammece, Mask., which attains a length of nearly $S$ mm. The present species resembles mammer in other characters, $e . g$., the structure of the antemme and legs; but Maskell makes no mention of a marginal fringe of hairs, nor of the cellular character of the derm. Maskell states that in mommece the tassal digitules are wanting. In maxima they are long, stont and distinetly knobbed.

Pulvinaria psibit, Mask.
On Coffea libevica (No. 4) and Ficus sp. (No. 9).
Ceroplastes cinrifipediformis, Comstock.
On Eugenia aquea (No. 6).
The specimens to hand are not in very good condition, but all the characters, as far as they can be seen, correspond very closely to those of Comstock's species. The anal opereulum is situated on a prominent

Fig. 3. conieal process. There are no marginal hairs, but at each stigmatic cleft is a group of about 25 conical spines, the extremities drawn out into sharp points (fig. 3). Comstock deseribes these spines as arrow-shaped and constricted at the base. As pointed ont in some "Observations on the genus Ceroplastes" (Ann. and Mag. Nat. Hist., Ser. 7, Vol. iv, September, 1899, pp. 190, 191), this stalked appearance is unreal, being produced by the subcutaneous tube leading inwards from the spines. There is a slight constriction at the base, but nothing that could be interpreted as pedicillate. In most of my specimens the very elongate 3rd joint of the antenne shows an imperfect division at about one-third its length from the base.

## Ceroplastes rinsonil, Sign.

On Hiptage laurifolia (No. 54).
Diaspis pentagona, Tirg.
On young plants of Eryflirina lithosperma (No. 3) and on 'thea assumica (No. 69).

## Diaspis rosm, Bouché.

On Rosa sp. (No. 44).
Ischnaspis longirostris, Sign.
On stems and leaves of Coffea liberica (No. 5); on Myristica fragrans (No. 39) ; and on Zalacca sp. (No. 40).

Parlatoria zizipines, Lucas.
On Citrus sp. (No. 14).
Farlatoria proteus, Curtis.
On Herea brasiliensis (No. 81).
Aspidiotus (Aonidiella) aurantit, Mask.
On Citrus sp. (No. 16) ; on Camphora offecinalis (No. 55) ; and on Cyeas sp. (No. 43).

Aspidiotes cyanopifllif, Sign.
On Theobroma cacao (No. 71).
Aspidiotus desthuctor, Sign.
On Bixa orellana (No. 67) ; Theobroma cacao (No. 71) ; Uncaria gambir, (No. 88) ; Vitis (No. 91) ; Cocos nucifera (No. 102).

Aspidiotus (Chrysompialus) dictyospermi, Morg.
On Diospyros (No. 29) ; Myristica fragrans (No. 42) ; and Palaquium sp. (No. 48).

Aspidiotus transparens, Green.
On Anomianthus heterocarpus (No. 65) ; Anona sp. (No. S9) ; and Hevea brasiliensis (No. 21a).

Aspidiotus (Cirysompinalus) ficus, Ashm.
On Croton sp. (No. 103).
Aspidiotus (Pseddaonidia) curculiginis, sp. nov. (fig. 4).
Female puparium superfieially resembling that of $A s p$. rossi. Elliptieal, flattish ; dark blackish-brown. Pellieles fulvous, slightly raised, with inconspieuous boss and eoncentrie ring, surrounded by a thin whitish line. Inner surface paler brown; ventral seale persisting along the margins.

Length, 2 to 2.50 mm . ; breadth, 1.25 to 1.50 mm .
Male puparium similar, but smaller; pellicle nearer the anterior extremity. Length, 1.50 mm . ; breadth, 0.80 mm .
Adult o reddish-fulvons (dried examples). Form resembling Asp. trilobitiformis or $A$. thex, with a deep constriction between the pro- and meso-thoracic
segments; broadest across the meso-thorax ; abdominal segnents well defined and produced at the margins. Extremity of pygidiun (fig. 4.) rather truncate, with

Fig. 4.
eight lobes; the median pair large, stout and conspicuous, extremity pointed, edge slightly incised on each side near the point ; the second and third pairs narrow and lauceclate, constricted at base; fourth pair short, stout, and with incised edges. Margin cristate beyond the lobes. Narrow fimbriate squames between the lobes. Margin somewhat incrassate, with numerous short thickened paraphyses. Median area of pygidiun, from apex to beyond anal aperture, darker and more densely chitinous. Circumgenital glands in four groups, each with about twelve orifices. Anterior spiracles with a small group of parastigmatic glands, containing three or four orifices.

Length, 1.25 mm . ; breadth, 0.90 mm .
Adult § not known.
Habitat: on both surfaces of leaves of Curculigo recurvata. Buitenzorg, Java (Coll. Zimm., No. 33).

Allied to Asp. theer and $A$. trilobitiformis, but with no tessellated patch on pygidium.

## Lepidosapies corrugata, sp. nov.

Female puparium dull black, thick and opaque; pellieles reddish-fulvous, exposed. Form normal, widening very gradually behind; outhe usually sinuous; somewhat flattened above, with mauy eurved tramserse corrugations. Ventral seale stout; persistent along the margin; usually interrupted along the median line.

Length, 3 to 4.50 mm .; greatest breadth, 1 mm .
Male puparium not observed.
Adult $\$$ of usual form ; broadest across abdominal segments, which are moderately produced at the margins. Anterior spiracles with a small group of parastigmatic glands. Median lobes of pygidium conspicuous, bluntly pointed, with irregularly crenulate or dentate edges. First lateral lobes small, thplex, the inner lobule the larger. Other lobes wanting. The usual spiniform squanes and marginal pores. Dorsal surface of pygidium with a conspicuous double series of oval pores extending on each side from level of amul nperture almost to margin, and two smaller series outside these. Cireumgenital glands in five groups: median group with six to seven orifices; upper laterals, 9 to 10 ; lower lateral, 8 to 9 .

Length, 1 to 1.25 mm .
Adult ठ not known.

Habitat: on stem of Coffea arabica. Java (Coll. Zimm., No. 27). The puparia are usually concealed beneath the superficial corky growth, and probably owe their flattened form to this habit.

This species belongs to the group of which M1. pomorum and $D I$. citricola may be taken as types. The stont flattened and corrugated puparium and the conspicuons double series of dorsal pores on the pygidium of the $q$, will serve to distinguish the present species from its nearer allies.

> (To be continued).

Odontrus mobilicornis, F., at Downham, Norfolk.-On July 13th, whilst moth catching, I took a fine male specimen of Odontrus mobilicornis, F., flying, just as it was dusk.-Robert S. Smith, Jumr., The Laurels, Downham: Aug. 7th, 1904.
[Many years ago Stephens recorded this speeies from Norfolk, so this capture is interesting as confirming his record.-W. W. F.].

Plagiodera versicolora, Laich., in abundance at Oxford.-This beetle is not usually regarded as at all common, and I never saw it alive until July 23 rd last, when it occurred in such numbers as to be considered almost as a pest. I met with it on this year's shoots, growing up from the stumps that had been lopped in the previous winter, of a willow hedge bordering the footpath to South Hinksey, only just outside the city of Oxford. Here for about 200 yards it could be seen in profusion, often five or six together on a single leaf, and the ravages of the beetle were conspicuons at quite a long distance off. It was accompanied by Phyllodecta vitellinx, L., and Crepidodera chloris, Fond., but both of these were in comparatively seanty numbers; its larve were also there, but not plentifully, I may add that I had passed the spot about three weeks previously, but had scen nothing of the Plagiodera in any stage, though I had swept the willows with my net. I shall be glad to distribute unset specimens of the beetle to any Coleopterist who may wish for them. James J. Walker, "Aorangi," Lonsdale Rcl., Summertown, Oxford : Aug. 8 th, 1904.

Triplax wnea, Schall., and T. russica, L., at Gibside.-Early in the morning (about $5.30 \mathrm{a} . \mathrm{m}$.) of July 8th, I found Triplax ænea, Schall., in some fungi growing on elm in Gibside. Returning with my friend Mr. Wallace on the evening of the 22nd, we shook some more fungi, and besides turning out several T. ænea, were lucky enough to come across T. russica, L., an insect hitherto unrecorded from the Northumberland and Durham district. On Saturday, the 24th, I examined this part of Gibside more closely, and soon found an elm overgrown with fungi to a height of about 20 feet, and not far from it a holly also overgrown; and made some observations, which may prove interesting.
T. ænea and T. russica occurred in almost equal numbers at the foot of the tree, whilst from a beight of over four feet $T$. renea had the advantage in uumbers, and at a height of over eight feet there were scarcely three examples of $T$. russica to fifty $T$. ænea! What is the reason?
